Earth System Science: The Big Ideas

Like all scientific disciplines, the Earth sciences continually evolve over time. New discoveries fuel new ideas, providing an ever-increasing understanding of the planet. But of the overwhelming number of observations, theories, and principles that form the foundation of Earth system science, what is essential for every American to understand? All too often, curricula are too ambitious and, as a result, may fail to cover topics in any substantial depth. An alternative approach is to build one’s curriculum upon a foundation of focused, interconnected big ideas. A well-designed set of big ideas can provide an all-encompassing conceptual framework for any discipline, including Earth system science. Developed alongside scientists and Earth science teachers, this coherent set of big ideas illuminates what is fundamental to the Earth sciences:

1. The Earth is a system of systems.
2. The flow of energy drives the cycling of matter.
3. Life, including human life, influences and is influenced by the environment.
4. Physical and chemical principles are unchanging and drive both gradual and rapid changes in the Earth system.
5. To understand (deep) time and the scale of space, models and maps are necessary.

These ideas are designed to cover the breadth of any Earth science curriculum, but they must be dissected to build deep understanding. Each idea is essentially bottomless; that is, while a meaningful understanding of these ideas is readily attainable, the details contained within are endless. Each of the ideas can be understood, but the depth of understanding can vary greatly.

Introduction of these ideas also invites discussion of the nature of science. As curricula are designed and implemented, the traditional topics of Earth system science should be complemented with ideas on how we have come to know what we know about the natural world. Within our big ideas framework, we draw attention to the nature of science with two overarching questions:

1. How do we know what we know?
2. How does what we know inform our decision making?

These questions, when addressed in concert with the big ideas, provide a gateway into the nature and utility of the range of scientific ideas.
Big Ideas

Big Idea 1: The Earth is a system of systems

The Earth is composed of many systems, which cycle and interact in both space and time. It is also part of a multitude of systems, nested in larger systems such as the solar system and the universe. Systems are composed of an untold number of interacting parts that follow simple rules; they can and do evolve. For example:

Outlining the geologic history of any region demonstrates the concept of the Earth as a system of systems. **Plate tectonics** drives the formation of mountains. Subsequent **weathering** and **erosion** of the **uplifted** mountains leads to the formation of **deltas** in adjacent shallow seas. And with uplifted continents, shorelines change and the distribution of marine communities are altered.

The planet’s systems are intimately connected: the forces of one system affect other systems nested within it. As **plates** collide, systems that drive plate tectonics are obviously linked to the formation of mountains, but they are ultimately linked to and influence much smaller systems. The intense **heat** and pressure resulting from collisions can lead to the **metamorphism** of existing strata, or it can melt existing rocks to later form **igneous rocks**.

As **glaciers** extended from the north during the **ice age**, they cut into river valleys. This glacial system shaped the landscape of upper North America, deepening and widening existing rivers and damming huge lakes that later emptied in great torrents. For example, Glacial Lake Missoula emptied in a catastrophic flood that carved out the Channeled Scablands in northern Idaho and eastern Washington while also leaving behind huge sediment deposits. Had glaciers never advanced this far south, the erosional forces that led to the formation and draining of these lakes would have never been set in motion. The interaction of **climate**, rock, and water has shaped every natural landscape on the planet. Humans and other living things build upon (or tear down) the foundations laid down by these systems, furthering their interplay.

See Chapter 6: Glaciers to learn more about glacial lakes, including Lake Missoula and Lake Agassiz.

Each of the remaining ideas operates across multiple systems within the larger Earth system.

---

**plate tectonics** • the process by which the plates of the Earth’s crust move and interact with one another at their boundaries.

**weathering** • the breakdown of rocks by physical or chemical means.

**erosion** • the transport of weathered materials.

**uplift** • upward movement of the crust due to compression, subduction, or mountain building.

**delta** • a typically wedge-shaped deposit formed as sediment is eroded from mountains and transported by streams across lower elevations.

**plates** • large, rigid pieces of the Earth’s crust and upper mantle, which move and interact with one another at their boundaries.

**heat** • a form of energy transferred from one body to another as a result of a difference in temperature or a change in phase.
**Big Idea 2: The flow of energy drives the cycling of matter**

The Earth is an open system. Energy flows and cycles through the system; matter cycles within it. This cycling is largely driven by the interaction of the differential distribution of solar radiation and internal heat: the constant flow of solar radiation powers much of Earth’s ocean and atmospheric processes on the surface of the system, while the flow of heat from radioactivity within the Earth drives plate tectonics. For example:

One of the fundamental processes known to Earth system scientists is the rock cycle. The rock cycle illustrates the steps involved in the formation of one type of rock from another. It is a system that has operated since the Earth’s origin, and it continues today. The energy that drives weathering and erosion, melting, or an increase in heat or pressure, drives the continuation of the rock cycle.

The landscape we see today in the Northwest Central has been shaped by the geologic forces of the past, and these forces are still active. The movement of Earth’s plates is driven by plate tectonics, illustrating how the flow of energy drives the cycling of matter—the flow of heat from radioactivity within the Earth drives plate tectonics. Evidence throughout the Northwest Central’s terrain tells a story that began billions of years ago with the formation of tectonic plates, and this story continues today. Plate tectonics played a significant role in the formation of the Rocky Mountains when upwelling mantle heat pushed the crust upwards around 68 million years ago. Today, thanks to a swath of fault zones in the Rockies and tectonic activity at the Yellowstone hot spot, the Rocky Mountains and Columbia Plateau regions comprise one of the most seismically active areas in the United States, with as many as 3,000 earthquakes occurring each year.

During the most recent ice age, glaciers advanced and retreated many times throughout the past two million years. One of the great questions in the Earth sciences revolves around the causes of these glacial cycles, with the general consensus pointing toward cyclic variations in the planet’s tilt, movement about its axis, and its orbital shape around the sun. These variations lead to changes in the amount of solar radiation that reaches the Earth, which in turn affect global climate.

The rock cycle, plate tectonics, and the water cycle are all convection-driven. Without convection, Earth would be extraordinarily different.
Big Idea 3:
*Life—including human life—influences and is influenced by the environment*

Across its four-billion-year history, the course of life’s evolution has been intimately tied to the Earth’s physical environment. Global cooling led to the relatively recent spread of grasslands, which then triggered an evolutionary shift in many herbivorous mammals from browsing to grazing. Conversely, the evolution of life has altered the physical environment. Photosynthetic bacteria released free oxygen into the early oceans and atmosphere, making Earth habitable for later types of organisms. Humans, with their increasing population and expanding technology, have altered the landscape and the distribution of flora and fauna, and they are changing atmospheric chemistry in ways that affect the climate. Earth system processes also influence where and how humans live. For example:

With human populations increasing the world over, the emission of **greenhouse gases** has also increased dramatically. These gases alter the chemical composition of the atmosphere and directly influence the planet’s climate. It is generally agreed that the rapid and immense pouring of carbon dioxide into the atmosphere will lead to **global warming**, which will have incredible impacts throughout the world.

Around three million years ago, a land bridge formed between North and South America. For the first time in more than 150 million years, the two continents were linked, and the mammals inhabiting both lands migrated across the bridge. Horses, mastodons, cats, and dogs moved south, while opossums, porcupines, ground sloths, and armadillos moved north (to name a few). Today, half the mammal species in South America are descended from North American migrants.

The Great Plains and Central Lowland regions, which make up the eastern portion of the Northwest Central, support extensive ranching and agriculture. The overwhelming majority of these regions are either under cultivation, used for grazing livestock, or developed for residential and commercial use. When we ask, “Why does this place look the way it does?” the role of humans must be central to our answer.
Big Idea 4: Physical and chemical principles are unchanging and drive both gradual and rapid changes in the Earth system

The Earth processes operating today—everything from local erosion to plate tectonics—are the same as those operating since they first arose in Earth history, and these processes are obedient to the laws of chemistry and physics. While the processes that constantly change the planet are essentially fixed, their rates are not. Tipping points are reached that can result in rapid changes cascading through Earth systems. For example:

During the Precambrian, the evolution of photosynthetic organisms led to significant changes in the planet’s atmosphere. Prior to this event, there was little free oxygen in the atmosphere, but with photosynthesis producing oxygen as a waste product, the very existence of these organisms flooded the seas and atmosphere with free oxygen, changing the planet forever. But life’s evolution represents just one of the processes working upon Earth systems.

Tectonic processes have been at work in the same way for billions of years, opening and closing oceans and building up and tearing down landscapes. The Yellowstone hot spot, currently located in Yellowstone National Park in northwestern Wyoming, is a mantle plume that has melted the crust (and induced volcanic eruptions) as the North American plate has passed over it. The trail of volcanic rock from these eruptions crosses southern Idaho, forming the Snake River Plain and ending at Yellowstone National Park. Major explosive caldera eruptions have occurred on a cycle of around 600,000 years—this recent geological history of volcanism has led the Yellowstone area to be classified as a supervolcano.

See Chapter 1: Geologic History for more about the tectonic processes that led to the formation of North America as we know it today.
Big Ideas

Big Idea 5: To understand (deep) time and the scale of space, models and maps are necessary

The use of models is fundamental to all of the Earth sciences. Maps and models aid in the understanding of aspects of the Earth system that are too big or small for direct observation, or where observation is not possible. They also help make complex systems comprehensible through strategic simplification. When compared to the size and age of the universe, humanity is a speck in space and a blip in time; models assist in the comprehension of time and space at both sub-microscopic and immense scales. For example:

Much of scientists’ understanding of the inner workings of our planet is derived from mathematical modeling. It is not possible to directly measure the movement that occurs below Earth’s surface, but modeling of convection currents brings us closer to the true nature of these monumental geologic phenomena.

The observation of natural phenomena today, such as deposition along a riverbed, is critical for interpreting the geologic record. But for processes that operate on much larger, slower scales, modeling within the lab is required. The formation of mountain ranges such as the Rocky Mountains is better understood by examining the effects of stress and strain in the laboratory.

What is the effect of a two-kilometer-thick (1.2-mile-thick) glacier on the terrain? In addition to changes related to deposition, the sheer weight of such an object depresses the continental mass. Understanding this compression—and the rebound that occurs upon the glacier’s retreat—is improved through modeling in the laboratory.
In Conclusion

Taken individually, these big ideas and overarching questions represent important aspects of Earth system science, but together they are more significant. Keeping these ideas in mind—and considering how they arose through scientific methods and investigation—is invaluable as one proceeds throughout his or her curriculum, and it can provide a conceptual framework upon which to build an enduring understanding of the discipline.
